ABSTRACT

Recent research pertaining to aerosol impacts on cloud microphysics has shown a need for understanding mineral dust entrainment into moist convection. The goal of this study is to examine the pathways in which non-microphysically active mineral dust is entrained into supercell storms within three commonly observed dust regimes. The Regional Atmospheric Modeling System (RAMS) with an interactive dust model that allows for surface emission was used to achieve this goal.

First, a supercell is simulated within an already dusty environment (EXP-BACKGROUND) to investigate ingestion purely from a background source. Second, the supercell is simulated within a clean background environment and lofts its own dust via the interactive dust model (EXP-STORM), to investigate the regime in which the only source of dust in the atmosphere is due to the storm itself. Finally, the supercell is simulated with a low-level convergence boundary introduced ahead of the supercell to investigate dust lofting by outflow boundary interactions (EXP-BOUNDARY). Results indicate that the supercell in EXP-BACKGROUND ingests large dust concentrations ahead of the rear-flank downdraft (RFD) cold pool. Conversely, dust lofted by the cold pool in EXP-STORM is ingested by the supercell in relatively small amounts via a narrow corridor generated by turbulent mixing of the RFD cold pool and ambient air. The addition of a convergence boundary in EXP-BOUNDARY is found to act as an additional source of dust for the supercell. Results demonstrate the importance of an appropriate dust representation for numerical modeling.
1. Introduction

Dust is likely the most abundant aerosol species in the atmosphere with global emission estimates ranging from 1,000 – 3,000 Tg yr\(^{-1}\) (IPCC 2001). It can alter the atmosphere in a variety of complex manners. Climatologically, dust directly impacts the radiative budget through the absorption and scattering of both shortwave and longwave radiation (Quijiano et al. 2000; Hansell et al. 2010). Additionally, dust indirectly affects the climate through aerosol indirect forcing that alters cloud properties and subsequent cloud radiative feedback effects (Twomey 1977; Albrecht 1989). On smaller scales, mineral dust can result in significant changes to the microphysical processes and associated precipitation rates of deep convective clouds by acting as cloud condensation nuclei (Levin et al. 1996; Rosenfeld and Nirel 1996; Feingold et al. 1999; Ramanathan et al. 2001; DeMott et al. 2003; Rosenfeld et al., 2001; Yin et al. 2002; van den Heever et al. 2006, 2011; Khain et al. 2005; 2008; Twohy et al. 2009; Storer et al. 2010) and ice nuclei (IN) (Isono et al. 1959; Roberts and Hallett, 1968; Zuberi et al. 2002; DeMott et al. 2003; Sassen et al. 2003; Field et al. 2006; Mohler et al. 2006; van den Heever et al., 2006). While it is well known that mineral dust impacts cloud microphysics by acting as nuclei, our understanding of the manner in which mineral dust is ingested into deep convective storms is not well understood. This is due in part to the numerous types of dust events in our atmosphere and the poor representation of these different events in modeling experiments that investigate dust impacts on atmospheric processes.

While all mineral dust in the atmosphere initially comes from surface lofting by strong winds (Tegen and Fung 1994; Liu et al. 2007), the vertical distribution and
concentrations of dust are different within specific meteorological events. First, the most prolific dust events occur due to large-scale dust lofting mechanisms, such as synoptic cyclones over deserts (Knippertz et al. 2007; Lewis et al. 2010), when mineral dust can be lofted higher than the boundary layer and transported over large distances. This mechanism can allow dust to behave as a well-mixed background aerosol. One example of this is the Saharan Air Layer (SAL), whereby a layer of Saharan dust has been found to affect convection as far west as the eastern United States (Prospero 1996, 1999; Perry et al. 1997; Sassen et al. 2003). The numerical representation of this dust regime, where dust is treated as a well-mixed background aerosol, is commonly used when studying dust impacts on convection (e.g. van den Heever et al. 2006, 2011; Zubler et al. 2011). A second commonly occurring dust regime occurs when convectively generated cold pools loft large concentrations of dust that are localized, being contained behind the gust front (Figure 1). These mesoscale dust storms, by which we mean the wall of dust within a cold pool (Figure 2), are commonly referred to as haboobs (Sutton 1925; Lawson 1971) and occur within and beyond the reaches of the largest desert regions in the world. Within arid regions it has been found that these mesoscale dust storms can account for up to 30% of the regional dust mass budget (Miller et al. 2008). However, few dust studies truly represent the lofting of dust by the cold pool in order to understand its impacts on parent convection (Tulet et al. 2010). A third dust regime occurs when several discrete thunderstorms in a region produce their own boundaries and dust storms that all interact (Droegemeier and Wilhelmson 1985). In this regime, developing or mature convection could have access to multiple localized sources of dust. However, the pathways and the extent of dust ingestion by storms within this regime have not yet been examined. These
various dust regimes demonstrate the complexities involved with correctly representing
dust transport and ingestion in a numerical model.

Observational studies have found large concentrations of dust within convection
(Levin et al. 1996; DeMott et al. 2003; Jensen et al. 2004; Twohy et al. 2009), however
collecting in situ dust ingestion data for these various regimes is extremely difficult and
dangerous as high concentrations of dust damage plane engine turbines and clog air
filtration systems (Miller et al. 2008). As a result, the method of obtaining a quantitative
assessment of these data has typically been through numerical analyses (Takemi 2005;
Tulet et al. 2010) using dust emission parameterizations that are shown to be accurate on
the global scale (Kang et al. 2011). However, the grid-spacing of global simulations make
it difficult to resolve the small-scale circulations and sharp gradients associated with the
cold pool that aid in dust lofting, transport, and subsequent ingestion by convection
(Marsham et al. 2008; Reinfried et al. 2009). Therefore, precise ingestion pathways into
the updraft of deep convective storms are still largely unknown.

The goal of this paper is therefore to gain a better understanding of the pathways
by which dust is ingested by mesoscale storms within commonly observed dust regimes
through the use of a high-resolution cloud-resolving model. To accomplish this goal, the
Regional Atmospheric Modeling System (RAMS) (Pielke et al. 1992; Cotton et al. 2003;
Saleeby and Cotton, 2004) coupled with an interactive dust model (Smith 2007) is used
to simulate a supercell thunderstorm within three commonly observed dust regimes. First,
we simulate an idealized supercell within a horizontally homogeneous background dust
profile to represent the ingestion of dust by a storm initiating within an already dusty
atmosphere (e.g. the SAL, referred to as EXP-BACKGROUND). Second, we simulate
the contribution and ingestion of mineral dust produced purely by the mechanics of the supercell itself (e.g. the haboob, referred to as EXP-STORM) by utilizing a surface dust emission scheme and an initially dust-free background environment. Third, an independent surface convergence boundary is added to the domain ahead of the supercell to investigate dust ingestion resulting directly from the interaction between the supercell-produced gust front and the imposed convergence boundary (e.g. haboob interactions, referred to as EXP-BOUNDARY). These three model experiments represent a range of possible dust pathways into convection for commonly occurring dust regimes. The results of these experiments will aid future investigations into dust impacts on precipitation processes by demonstrating the sensitivity that differing dust sources has on ingested dust concentrations and locations.

The following section briefly describes the model used for these simulations with emphasis placed on pertinent schemes and the numerical setup for each experiment. Section 3 presents results from all three experiments and Section 4 provides discussion and conclusions of the results from each experiment. This paper is the first in a series of experiments dedicated to the understanding of mineral dust ingestion and its impact on the parent convection. The goal of this first paper is solely to understand the ingestion pathway of mineral dust into the lower region of a supercell within common dust regimes. Therefore, mineral dust in this experiment is not microphysically active. The remaining experiments in this series of papers will investigate the microphysical and radiative impacts of ingested dust on deep convection and will be reported on elsewhere.
2. Methods

a. Model description

The numerical model that was used for this study is the non-hydrostatic RAMS model (Pielke et al. 1992; Cotton et al. 2003; Saleeby and Cotton, 2004), which uses a staggered Arakawa-C grid. RAMS is appropriate for this numerical study because of its sophisticated microphysical, surface and mineral dust parameterization schemes. The two-moment microphysical scheme (Meyers et al. 1997) predicts both mass mixing ratio and number concentrations of the hydrometeor species. The water species are categorized in eight forms: vapor, cloud droplets, rain, pristine ice, snow, aggregates, graupel and hail (Walko et al. 1995). Within each category, the hydrometeors are assumed to conform to a generalized gamma distribution (Flatau et al. 1989; Verlinde et al. 1990). The bulk microphysical schemes within RAMS contain added sophistication by accessing previously generated lookup tables for the nucleation of aerosol species such as CCN, giant cloud condensation nuclei (GCCN), and IN. The reader is referred to Saleeby and Cotton (2004) for a detailed description regarding the activation of CCN and GCCN, and Meyers et al. (1997) regarding IN.

At the surface, RAMS divides each grid cell into a patchwork of water, bare soil, and vegetation over shaded soil that interacts with an online surface model, LEAF3 (Walko et al. 1995). For these experiments bare soil was chosen to represent 100% of each grid cell as we are examining dust storm development in arid regions.

Surface and soil studies have provided the information necessary to construct a
model containing reliable surface dust emission, deposition and transport within RAMS
that communicates online with LEAF3 (Smith 2007). Dust emission is diagnosed only
when a surface wind velocity threshold value is reached and is a function of surface wind
speed, soil type, and soil moisture (Marticorena and Bergametti 1995; Fecan et al. 1999).
The wind threshold velocity for dust lofting is strongly dependent on particle diameter,
therefore the user must choose a soil size distribution to represent bare soil. For this
experiment the soil distribution is based on Tegen and Fung (1994) and contains only silt
and clay. The dust particle size distribution is partitioned into seven size increments,
where sizes 1-4 represent clay and sizes 5-7 represent silt (Table 1). With respect to mass,
silt constitutes 90% of the erodible materials, while clay is responsible for the remaining
10%. The partitioning of dust into multiple sizes allows for a more accurate
representation of surface dust lofting.

If the wind speed at 10 m is greater than the computed wind threshold over moist
soil ($U_{twet}$) and soil volumetric moisture content is less than 50% of saturation, then dust
is allowed to be lofted from the surface. The amount of dust mass emitted from the
surface is parameterized as a mass flux that is a function of 10m wind speed and wind
threshold velocty (Gillette and Passy 1988; Ginoux et al. 2001). From the mass flux,
number concentrations for each particle size are computed using an assumed density of
2500 kg m$^{-3}$ for clay and 2650 kg m$^{-3}$ for silt (Tegen and Fung 1994). Finally, the
concentrations for each clay size are summed up and added to the existing concentrations
for clay species (referred to as the small dust mode), while the same procedure is
performed for the silt species (referred to as the large dust mode). This summation
results in a single concentration for both the small and large dust mode. After lofting, the
subsequent dust removal and transport schemes perform calculations with respect to these two modes. This results in a two bin representation of dust within RAMS.

The removal mechanisms of each dust mode within the model include gravitational settling (Baron and Willeke 2001) and below-cloud scavenging by precipitation for all model levels below cloud base (Slinn 1981). The reader is referred to Smith (2007) for a more detailed summary of these parameterizations. Research is currently underway to develop parameterization schemes representing the scavenging and nucleation of mineral dust to form cloud droplets and ice crystals within cloud. As such, mineral dust in this experiment is not microphysically active and is simply used as an active tracer to investigate ingestion by supercell storms. As the goal of this paper is to investigate mineral dust ingestion into supercells this should not significantly impact the results.

b. Experimental design

In this study, three idealized simulations are performed of a supercell to understand how mineral dust becomes entrained into such storms. To best resolve the cold pool and turbulent eddies responsible for dust lofting and transport, RAMS is configured as a high-resolution cloud resolving model (CRM). Table 2 summarizes the model configuration for all simulations. The horizontal grid has a spacing of 300 m and the vertical grid spacing closest to the surface is 25 m and increases by 10% for each higher model level until a maximum of 300 m is reached, above which it stays at 300 m.
To initiate convection, a 10 km wide, 2 km deep warm bubble containing a uniform thermal perturbation of 2 K (Table 2) is used within a convective environment following Weismann and Klemp (1982) (Figure 3). In addition to the thermodynamic profile, the veering wind profile favors the development of a right moving supercell (Weismann and Klemp 1984). Supercell evolution within each experiment is identical. The following subsections briefly describe the dust regime used for each model experiment, the details of which are summarized in Table 3. For cloud and ice nucleation within all experiments, background concentrations of 1600 cm$^{-3}$ and 10,000 kg$^{-1}$ are used for aerosol species that can be activated as CCN and IN, respectively (Table 2). These aerosols are independent of the dust species.

1. EXP-BACKGROUND

For this experiment, the surface dust emission parameterization is turned off and an initial horizontally homogeneous environmental profile of dust (Figure 4) is used to represent the development of supercells within an already dusty environment. The vertical profile used to initialize the model consists of a surface concentration of 1000 cm$^{-3}$ that linearly decreases to 20 cm$^{-3}$ by 4 km AGL and is then held fixed at 20 cm$^{-3}$ within the remainder of the domain. This vertical profile was chosen following observations documented by Chen and Fryrear (2002) of a mid-latitude haboob in Big Spring, Texas. They measured a maximum concentration within 15 m of the surface of $1.3 \times 10^3$ µg m$^{-3}$ which, when using a mean particle diameter of 0.8µm and a density of 2500 kg m$^{-3}$ (small dust mode) produces a particle number concentration of $\sim 1250$ cm$^{-3}$. 
Surface dust emission is absent in this experiment, however the remaining schemes within the dust model are still active, including dry deposition and below-cloud scavenging by precipitation.

2. EXP-STORM

In order to examine the contribution of ingested dust following lofting purely by the supercell itself, this simulation initially contains no background dust. The surface dust emission within the dust model is enabled. With no initial background dust (unlike EXP-BACKGROUND), all dust produced in this experiment originates from the surface. This provides a means to assess dust ingestion pathways into a supercell of that dust produced purely by the storm’s own kinematics.

3. EXP-BOUNDARY

The aim of this experiment is to further our understanding of mineral dust ingestion as a direct result of outflow boundary interactions. The numerical setup of this experiment is identical to EXP-STORM (full dust model and no initial background dust), except that 95 minutes after initialization, an independent surface convergence boundary is introduced ahead of the supercell outflow boundary. The addition of the surface convergence boundary at this time allows for (1) sufficient time for numerical stabilization of the boundary, and (2) the interaction with the supercell outflow boundary during the analysis times of the other two experiments, thus facilitating experiment
comparisons. This additional convergence boundary will also contribute to lofted dust within the environment, thus making it potentially available for ingestion by the supercell, similar to what you might see in reality in an environment populated by numerous discrete storms. The convergence boundary is initialized by instantaneously inserting a north-south oriented -5K thermal perturbation that is 1 km deep (surface to 1 km AGL) and positioned 20 km ahead of the approaching right moving supercell. The cold, dense air generates two horizontally propagating outflow boundaries – one to the east and one to the west. The depth and temperature perturbation were chosen through trial-and-error in order to produce surface wind speeds and lofted dust concentrations similar to that produced by the supercell itself in EXP-STORM, thereby allowing for appropriate comparisons between experiments. The western outflow boundary of the convergence zone interacts with the supercell gust front and will be the focus of analysis. The following section first presents results pertaining to the supercell evolution for all three experiments and is followed by specific results from the three experiments just described.

3. Results

a. Supercell evolution and analysis

As mentioned in the previous section, a warm bubble is used to initiate convection. After 45 minutes, the main updraft shows signs of splitting into a right and left mover (Klemp and Wilhelmson 1978b) due to the strong vertical wind shear of the
environment (Weisman and Klemp 1982). To demonstrate the evolution of the split, Figure 5 shows convection after 55, 85, 115, and 145 minutes into the simulation. The filled contours are model emulated radar reflectivity at the lowest model level (~ 12 m AGL) to emphasize surface characteristics, and which has been calculated following the methodology of Matrosov (1999). After 85 minutes the split can be seen in the surface reflectivity field with a clear separation in maximum dBZ. By 115 minutes, the right moving supercell has taken on the appearance of a classic cyclonically rotating supercell (Weisman and Klemp 1984), where a hook is evident in both the reflectivity field and cold pool boundary on the southern flank of the storm. Thirty minutes later, the right mover is still well organized and is the dominant supercell due to the veering wind profile imposed (Weisman and Klemp 1984). The path of the supercells can be seen via the accumulated surface precipitation (Figure 5), where a right turn is evident in the southernmost cell. The cold pool boundary has been calculated following the methodology of Tompkins (2001) where the cold pool is defined by air with -0.04 m^2 s^-1 buoyancy relative to the domain averaged buoyancy at the desired model level. Because the right moving supercell is the dominant cell simulated and the structure remained stable throughout the simulations, all analysis in this section is in regard to the right moving supercell.

During analysis of the right moving supercell, a 15-minute period demonstrated strong cold pool forcing that generated a hook feature in the precipitation fields. Figure 6a-d shows the cold pool (thick black contour) shape and characteristics during this time period after 105, 110, 115, and 120 minutes, respectively. It can be seen in Figure 6a-d that after 120 minutes the southern portion of the cold pool pushes farther east than the
cold pool region to the north as a result of being driven by a surge of air from the rear flank downdraft (RFD) (Markowski 2002). This surge has reached the gust front and can be seen in the surface wind field (thin solid contours), whereby a small portion of >12 m s\(^{-1}\) winds have been pushed ahead of the main surface wind maximum. This local wind maximum along the RFD gust front is also associated with a tongue of colder air (shaded contours) that is aiding in forcing the RFD gust front through baroclinic generation of horizontal vorticity (Markowski 2003). The RFD surge seen in this 15-minute period produces the hook shape in both cold pool and surface reflectivity that is a typical characteristic of a supercell. It is hypothesized that when a hook signature is present, this is the most likely time period that tornadogenesis can take place as RFD-produced vorticity can be coupled with the supercell low-level mesocyclone (Markowski et al. 2008). This coupling aids in the collocation of the surface and cloud-base updrafts, which in turn would assist with dust ingestion. Thus, the time period from 105 to 120 minutes, which encompasses the development of the hook echo, will serve as the focus of this analysis.

Additionally, it is important to mention that dust analysis presented herein is with respect to the small dust mode. This mode has been chosen as analysis showed dust ingestion pathways between the small and large dust modes to be virtually the same. As the focus of this paper is on the ingestion pathways into the storm, presentation of both dust modes is redundant.

\( b. \) EXP-BACKGROUND
This experiment examines supercell development in a dusty environment with no contribution from surface lofting. To illustrate the three-dimensional nature of dust ingestion, Figures 7 and 8 show various two-dimensional cross sections (at 105min and 120 min, respectively). Unless otherwise stated, all dust concentrations are shown as concentrations relative to background levels (i.e. the initial dust profile imposed), which provides a more representative assessment of ingestion.

Beginning at the surface, Figure 7a shows a plan-view of the mineral dust distribution, cold pool boundary, and wind flow associated with the right moving supercell. It can be seen that within the RFD cold pool, the dust concentrations are significantly lower than the low-level ambient concentrations of dust. This is due to the advection of less dusty air from aloft to the surface by the storm downdraft. As the RFD transports less dusty air, the surface wind spreads this “cleaner” air mass throughout the cold pool, while the remainder of the surface air contains near background levels of dust.

Moving higher aloft towards cloud base, which is located around 1800 m AGL, Figure 7b shows a plan-view at 2 km AGL illustrating the dust distribution and upward and downward fluxes associated with the updraft and downdraft of the supercell, respectively. The dust concentration and dust flux fields together demonstrate dust ingestion near cloud base. The positive flux values in conjunction with elevated dust concentrations illustrate the region of maximum dust ingestion, whereby updraft air is advecting higher concentrations of dust from below cloud base into the storm. Conversely, regions of large negative fluxes depict the region of the storm that is transporting dust from within the storm to lower levels. It can be seen that the area of largest positive vertical flux at 2 km AGL occurs ahead of the maximum dust
concentration at this level, while the largest negative vertical flux occurs behind the maximum concentration. This signature shows the motion and ingestion of the supercell – as the supercell propagates towards the east, the updraft atop the surface cold pool raises the dust concentration (shown by large fluxes) and shifts the dust distribution and concentration maximum farther east.

To further illustrate the flow regime and ingestion within the region of largest dust concentrations, Figure 7c shows an east-west vertical cross section through the 2 km AGL maximum dust concentration. From this figure it can be seen that a large region of elevated dust concentrations exists, however the largest elevated dust concentrations at any vertical level still remain within the updraft while the lowest elevated concentrations are confined to the downdraft. The upward vertical motion ahead of the cold pool and just below cloud base (i.e. the main updraft) is occurring where large elevated dust concentrations are present. This indicates that the transport of dust into the parent storm in this case occurs due to the updraft within the top of the boundary layer, where vertical motion and high dust concentrations are co-located.

To isolate the contributions of dust ingestion due to the horizontal and vertical components of the wind, Figure 7d shows upward dust flux in the shaded contours and horizontal dust flux in vector form, where the length of the vector indicates the magnitude of the horizontal dust flux (maximum value is ~ 14 cm$^{-2}$ s$^{-1}$) and the vector direction indicates flux direction in the x-y plane through the cross-sectional surface. To best isolate dust ingestion into the storm, which is the primary focus of this experiment, the flux values within the cold pool and associated with the downdraft are removed from the figure for this analysis. The vertical cross-section location, cold pool boundary, and
condensate boundary in 7d are the same region as in Figure 7c. Within the main updraft, dust is fluxed both vertically and towards the northwest. Conversely, within the backside of the updraft and the downdraft dust is being advected from the east and northeast, respectively. This cyclonic turning of the advective motion is in agreement with the typical cyclonic circulation of right moving supercells (Weisman and Klemp 1982). As previously mentioned, the majority of the dust ingestion in this experiment after 105 minutes occurs out ahead of the cold pool from the upper portion of the boundary layer into the updraft. This is reinforced quantitatively in Figure 7d by the relative values of upward dust flux and horizontal dust flux. The large spatial coverage of upward dust flux into cloud base is co-located with the updraft of the storm, similar to 7c, and has values on the order of $1000 \times 10^3 \text{ cm}^{-2} \text{ s}^{-1}$. Conversely, horizontal dust flux, which can be related to lateral entrainment, has maximum values on the order of $10 \times 10^3 \text{ cm}^{-2} \text{ s}^{-1}$ near the center of the updraft and decreases toward cloud boundary. The two orders of magnitude difference between the vertical and horizontal dust flux shows that dust ingestion is mainly driven by the vertical component of the wind, i.e. the updraft.

Figure 8 is identical to Figure 7, except for 120 minutes into the simulation, which is the time at which the RFD gust front has strongly pushed ahead of the northern gust front in a hook shape, as described earlier. When comparing the two figures, the magnitudes and characteristics of the quantities plotted are virtually the same, indicating that even after strong cold pool forcing has occurred, dust ingestion into the updraft remains virtually the same. While the storm updraft strength within the boundary layer may be dependent on the cold pool, this 15-minute period indicates ingestion of background dust by the supercell is somewhat independent of the cold pool forcing, as
long as the updraft has access to the dusty environmental air near the top of the boundary layer out ahead of the storm.

To more precisely identify dust ingestion into supercells from a dusty atmosphere, Figure 9 shows parcel trajectories into the supercell during this 15-minute period. These offline parcel trajectories are calculated using model data with a temporal resolution of one minute that are spatially and temporally interpolated to 10 m and 1 second, respectively, to allow for more precise trajectories. The trajectory calculations are performed following the resolved flow fields and do not include the effects of dust sedimentation, which is a reasonable assumption for vertical speeds associated with supercells. Figures 9a and 9b show parcel initialization at 105 minutes relative to the surface and the dashed vertical plane (depicted in 9a), respectively. After hundreds of parcel releases, twenty parcels most representative of both cold pool and environmental air at different heights AGL are shown in their respective horizontal and vertical locations (Figures 9a and 9b). After 15 minutes of trajectory analysis, the final locations of the twenty parcels are shown in 9c and 9d relative to the horizontal and vertical planes, respectively. The parcels that were ingested deep into the updraft were initially located ahead of the cold pool and well above the surface, therefore confirming the dust ingestion pathway of environmental dust by the supercell from the top of the boundary layer ahead of the cold pool and into the updraft.

c.  

EXP-STORM
The purpose of the second experiment is to examine the ingestion of dust lofted purely by the supercell itself. This is achieved by modeling the storm within an initially dust free environment and making use of the dust emission scheme to allow for the lofting of dust by the winds within the cold pool. Figures 10 and 11 show the same plots (at 105 min and 120 min, respectively) as Figures 7 and 8.

At 105 minutes into the simulation, the surface distribution of dust (Figure 10a) is closely linked to that of the surface winds (maximum plotted vector is $\sim 21 \text{ m s}^{-1}$), as dust lofting is strongly dependent on the 10 m wind speed. The strong surface winds that are generated by the RFD loft and transport the mineral dust within the RFD cold pool, distributing the dust both horizontally (Figure 10a) and vertically (Figure 10c). As shown in Figure 10a, the range of maximum lofted dust concentrations are $\sim 1100-1700 \text{ cm}^{-3}$, which are relatively consistent with haboob observations from Chen and Fryrear (2002) who measured 15 m AGL dust concentrations of $\sim 1250 \text{ cm}^{-3}$. Although the maximum simulated surface dust concentrations are larger than the haboob observations, it is to be expected given that the supercell simulated in this experiment produced surface winds in excess of 20 m s$^{-1}$ while the haboob only produced a maximum surface wind of 14 m s$^{-1}$.

As the dusty cold pool propagates within the ambient air, turbulent mixing at the leading edge of the RFD cold pool allows the dusty air to become mixed with the unstable environmental air (Figure 1) and associated low-level updraft (as will be seen later in this section). The dusty air at the leading edge of the RFD cold pool is detrained from the cold pool and forced into the rearward portion of the main updraft of the supercell. This produces a 2 km AGL maximum dust concentration of $\sim 30 \text{ cm}^{-3}$ (Figure 10b) from a pathway closely tied to the RFD gust front (Figure 10d). Even though the
cold pool in EXP-STORM produces surface dust concentrations larger than the
maximum background concentration in EXP-BACKGROUND, significantly lower
concentrations are ingested into the updraft of EXP-STORM (~ 30 cm$^{-3}$) compared with
that in EXP-BACKGROUND (~ 500 cm$^{-3}$). Additionally, the horizontal spatial extent of
the vertical dust flux (Figure 10d) is very narrow in comparison with EXP-
BACKGROUND (Figures 7d and 8d). The large differences in both magnitude and
spatial extent of ingested dust between EXP-STORM and EXP-BACKGROUND
demonstrates how difficult it is for a supercell to ingest dust produced by its own cold
pool as opposed to dust that is available from the ambient environment. While haboobs
are associated with large concentrations of dust kicked up within the cold pool, the
majority of this dust may not make it into the parent storm’s updraft.

After 120 minutes of simulation time (Figure 11), the dust ingestion pathway has
shifted further north as a result of the RFD surge that generated the hook echo. As the
RFD winds surged further east relative to the forward-flank downdraft (FFD), the low-
level winds formed a vertically stacked circulation (note the more upright distribution of
upward dust flux in Figure 11d versus Figure 10d) beneath the 2 km AGL maximum dust
concentration that closely resembles the location of classical supercell tornadogenesis
(Lemon and Doswell 1979; Markowski 2002; Lerach et al. 2008; Snook and Xue 2008).
This new region, which is still closely tied to the gust front (Figure 11d), advects
approximately two times more dust into the updraft as compared with 15 minutes earlier
(Figure 10) and contains much larger vertical fluxes. Similar to EXP-BACKGROUND,
the relative contributions of horizontal (values near cloud base are ~ 1 x 10$^3$ cm$^{-2}$ s$^{-1}$) and
vertical dust fluxes (values near cloud base are ~ 30 x 10$^3$ cm$^{-2}$ s$^{-1}$) to dust ingestion
shows that dust ingestion is dominated by the vertical wind. While the horizontal location of maximum dust ingestion changes between 105 and 120 minutes, the dependency on the RFD cold pool boundary remains consistent, and ingestion into the rearward portion of the updraft occurs at the cold pool and ambient air interface. Although the dust concentrations ingested by the supercell have doubled by this time, they remain an order of magnitude smaller than the dust concentrations ingested by EXP-BACKGROUND, thus further demonstrating the difficulty for cold pool-produced dust to become ingested by the parent supercell.

To more precisely identify dust ingestion pathways into supercells from dust originating at the surface within the cold pool, Figure 12 shows parcel trajectories into the supercell during this 15-minute period. Similar to Figure 9, Figures 12a and 12b show twenty parcels that best represent the transport processes occurring in the cold pool and at the gust front where dust is present. The parcels are initialized at 105 minutes relative to the horizontal and the vertical plane using the same methodology for EXP-BACKGROUND trajectory analysis. The final locations of the twenty parcels are shown in 12c and 12d relative to the horizontal and vertical planes, respectively.

Results from this trajectory analysis coincide with results shown in Figures 10 and 11. The only parcel to be ingested by the supercell and transported higher than 4 km AGL originated from within the cold pool, as shown by the 300 m AGL darkest blue parcel, confirming the cold pool origin of ingested dust by the supercell. At the start of the 15-minute trajectory analysis, the ingested parcel was located near the RFD surge (shown by large wind vectors within cold pool of Figure 12a and 12b) where increased convergence was occurring. The increased convergence (not shown) enhanced the turbulent mixing...
along its pathway thereby allowing detrainment of this parcel from the cold pool into the updraft where it is subsequently ingested by the supercell. For EXP-STORM, these trajectories confirm the aforementioned results that dust ingested by the supercell originates within the RFD cold pool winds and is detrained at the gust front surface, resulting in entrainment within the rearward portion of the updraft.

d. **EXP-BOUNDARY**

To further study the ingestion of dust by supercell storms within common dust regimes, the third experiment aims to investigate the influence of an additional surface convergence boundary on dust ingestion. This is an important experiment because several supercells or deep convective storms commonly form within the same environment, resulting in numerous boundary collisions (Bluestein and Weisman 2000). Figures 13, 14 and 15 show similar plots as Figures 10 and 11, but because the boundary interaction takes place relatively quickly, the times presented are at 105, 107, and 109 minutes into the simulation, respectively.

Ten minutes after the boundary initialization (Figure 13) the surface boundary can be seen to the east of the supercell cold pool. The convergence boundary has surface dust lofting (Figures 13 a and c) comparable to the leading edge of the RFD gust front, with maximum values of ~ 700 cm$^{-3}$. Additionally, the convergence boundary is advecting dust into the boundary layer air ahead of the supercell, both horizontally and vertically (Figure 13d). As the boundary collides with the supercell gust front at 107 minutes (Figure 14), interaction can be seen first near the surface, where the distribution of dust
within the supercell cold pool and the convergence boundary cold pool appear to merge (Figure 14c). While dust is being ingested in a similar fashion to EXP-STORM via the supercell RFD cold pool, dust can also be seen beginning to enter the supercell near cloud base farther ahead of the RFD cold pool (Figure 14 b and d), providing an additional dust ingestion pathway into the supercell at this time. As the convergence boundary lofts dust into the boundary layer air ahead of the supercell, the supercell updraft begins to ingest the dusty environmental air through a similar pathway as EXP-BACKGROUND. Two minutes later (Figure 15), full boundary interaction has taken place and the 2 km AGL concentration values have doubled due to the combination of boundary- and supercell-forced ingestion. Vertical advection of dust has also increased both in magnitude and height AGL because of (1) increased concentrations of dust due to the combination of RFD and convergence boundary produced dust, and (2) the enhanced updraft as a result of the boundary collision (Droegemeier and Wilhelmson 1985). The plume of mineral dust that has been ingested into the main updraft of the supercell as a result of the boundary interaction can be seen in Figure 15c, where a “tower” of >50 cm$^{-3}$ is present. After this time (109 minutes), the supercell propagates over the cooler and more stable air in the wake of the convergence boundary and this leads to weakening and eventual dissipation of the supercell. 

Using the same analysis as previously, parcel trajectories for this simulation are shown in Figure 16. In general, the parcels that were ingested into the main updraft of the supercell as a result of the boundary collision originated primarily from the ambient air (dark red and dark blue parcels in Figures 16 c and d). As shown with Figures 13-15, dust lofted by the imposed convergence boundary is advected into the ambient air.
through westward and vertical advection at the gust front. This advected dust is then ingested into the supercell updraft prior to the arrival of the supercell cold pool. These trajectories (Figure 16) confirm the aforementioned results of this experiment that for this environmental regime dust ingested into the supercell is enhanced by dust within the ambient air ahead of the supercell cold pool that is generated by the convergence boundary.

4. Discussion and conclusions

The overall goal of this experiment is to gain a better understanding of mineral dust ingestion pathways into severe convective storms. The three simulations performed in this experiment were designed to emulate some of the more common environmental regimes that provide a source of dust for ingestion by supercell storms. The first simulation, EXP-BACKGROUND, investigated a regime in which a supercell develops in an already dusty atmosphere in order to examine dust ingestion by the supercell solely from the environment. Conversely, EXP-STORM explored the regime in which a supercell develops in a dust free environment and the only dust available for ingestion is generated by the supercell itself. Lastly, EXP-BOUNDARY investigated dust ingestion pathways within the regime of a convergence boundary interacting with a supercell whereby both phenomena loft their own dust within an initially clean environment. The three dust regimes simulated in this experiment provide a range of possible dust pathways into convective storms and represent common dust environments observed in reality and utilized in numerical investigations.
The results of the three simulations demonstrate substantial differences in the location and quantity of dust ingested by the supercell. If the only source of dust is within the environmental air (i.e. EXP-BACKGROUND) then relatively large amounts of dust originating from upper region of the boundary layer ahead of the cold pool is ingested predominantly by the vertical component of the supercell updraft. Conversely, if the atmosphere is originally void of mineral dust and the only dust lofted into the atmosphere is due to the kinematics of the supercell cold pool (i.e. EXP-STORM), then relatively small concentrations of are ingested by the supercell via a very narrow region at the edge of the RFD cold pool. Dusty cold pool air is detrained at the interface between the cold pool and the ambient air and then entrained into the rearward portion of the updraft just ahead of the gust front. When investigating the influence of a convergence boundary on dust ingestion (i.e. EXP-BOUNDARY), it is seen that boundary interactions with supercells can enhance mineral dust ingestion in an initially clean environment by (1) acting as a source of background dust out ahead of the cold pool beneath the updraft, and (2) by enhancing the strength of the updraft and hence vertical advection as a result of the collision. These experiments show that large differences can arise in the manner in which dust is ingested by supercell storms, as well as in the concentrations of the ingested dust. This also demonstrates the necessity of an appropriate dust representation for numerical investigations.

While this study is not the first to our knowledge to directly simulate a mesoscale dust storm using a dust emission scheme, it is the first experiment that directly investigates and compares dust ingestion contributions from different production sources. Takemi (2005) simulated an idealized squall line in the Gobi Desert with 2 km grid
spacing in order to study mineral dust transport from dust produced by the cold pool. He concluded that strong cold pool wind is the source of mineral dust lofting, and that turbulence at the leading edge of the cold pool acts to detrain dust out of the cold pool and into the updraft at the cold pool edge. Additionally, Tulet et al. (2010) simulated mesoscale convective systems (MCS) with a finest grid spacing of 3 km over Niger and found a similar mechanism for dust entrainment into the parent convection. The dust lofting and ingestion process found in these studies are in agreement with the EXP-STORM results shown in this paper. The amount of dust ingested relative to dust lofted in Takemi (2005) and Tulet et al. (2010) is approximately 10%, which is also exhibited here in EXP-STORM. This provides increased confidence in the kinematic mechanism of dust ingestion by storms from cold pool lofting within a clean atmosphere. However as previously mentioned, the dust regime simulated by Takemi (2005) and Tulet et al. (2010) of a convective complex lofting and ingesting dust within an initially clean environment is only one common regime.

As shown in this paper, deep convection propagating within an initially dusty atmosphere can dramatically enhance ingested dust concentrations, whereby the ratio of dust ingested to the largest background concentration is close to 1. In EXP-BACKGROUND the environment initially contained 1000 cm$^{-3}$ of dust near the surface and the supercell contained ~ 1000 cm$^{-3}$ in the updraft at 4 km AGL. This contribution to the storm is significantly larger than exhibited in EXP-STORM and the experiments of Takemi (2005) and Tulet et al. (2010). Such variations in the dust concentrations can significantly impact the microphysical responses of precipitation processes (van den Heever et al. 2006). Additionally, this paper has shown that nearby convergence
boundaries can further complicate the method of dust ingestion by a supercell storm by providing an additional source of environmental dust. The large differences in ingested dust concentrations between the three simulations presented in this paper demonstrate (1) how efficiently a supercell propagating within a dusty atmosphere ingests mineral dust; (2) the relative difficulty of a supercell being able to ingest its own lofted dust; (3) the role additional surface boundaries play in enhancing dust ingestion by the parent storm, and (4) the importance of choosing an appropriate dust initialization method when simulating dust storms. Although it is known that mineral dust acts effectively as CCN and IN (Twohy et al., 2009), the mineral dust simulated in this experiment is not microphysically active. As such, the analysis presented in this paper only pertains to the ingestion pathway of dust into supercell storms and the relative amounts of dust ingested depending on the dust source. Research is currently in progress to allow dust to nucleate to form cloud droplets and ice. This will permit analysis of the microphysical implications of mineral dust ingestion within common dust regimes, along with analysis pertaining to vertical dust redistribution and radiative effects.
